## NOAA TECHNICAL REPORTS

## National Marine Fisheries Service, Special Scientific Report-Fisheries Series

The major responsibilities of the National Marine Fisheries Service (NMFS) are to monitor and assess the abundance and geographic distribution of fishery resources, to understand and predict fluctuations in the quantity and distribution of these resources, and to establish levels for optimum use of the resources. NMFS is also charged with the development and implementation of policies for managing national fishing grounds, development and enforcement of domestic NMFS is also charged with the development and implementation of policies for managing national fishing grounds, development and enforcement of domestic fisheries regulations, surveillance of foreign fishing off United States coastal waters, and the development and enforcement of international fishery agreements and policies. NMFS also assists the fishing industry through marketing service and economic analysis programs, and mortgage insurance and vessel construction subsidies. It collects, analyzes, and publishes statistics on various phases of the industry.

The Special Scientific Report—Fisheries series was established in 1949. The series carries reports on scientific investigations that document long-term continuing programs of NMFS, or intensive scientific reports on studies of restricted scope. The reports may deal with applied fishery problems. The series is also used as a medium for the publication of bibliographies of a specialized scientific nature.

NOAA Technical Reports NMFS SSRF are available free in limited numbers to governmental agencies, both Federal and State. They are also available in exchange for other scientific and technical publications in the marine sciences. Individual copies may be obtained (unless otherwise noted) from D83, Technical Information Division, Environmental Science Information Center, NOAA, Washington, D.C. 20235. Recent SSRF's are:

# Length Composition of Yellowfin, Skipjack, and Bigeye Tunas Caught in the Eastern Tropical Atlantic by American Purse Seiners

GARY T. SAKAGAWA, 1 ATILIO L. COAN, 1 and EUGENE P. HOLZAPFEL2

#### ABSTRACT

Sampling and analytical procedures that are used to estimate the size composition of Atlantic tunas caught by American purse seiners in the eastern tropical Atlantic are described. The procedures are based on a stratified, two-stage subsampling model. Estimates indicated that about 0.2 to 1.4 million yellowfin tuna, Thunnus albacares, 1.2 to 12.8 million skipjack tuna, Katsuwonus pelamis, and 0.5 to 41.2 thousand bigeye tuna, T. obesus were caught annually by the fleet in 1968-74. The dominant age group in most years was 1-yr olds for yellowfin and skipjack tuna and 2-yr olds for bigeye tuna.

## INTRODUCTION

United States participation in the eastern tropical Atlantic tuna fishery off west Africa began in the 1950's. It was not until 1967, however, that significant numbers of U.S. purse seiners entered the fishery (Sakagawa and Lenarz 1972; Sakagawa 1974). Since then as many as 36 American<sup>3</sup> seiners have participated annually in the fishery.

The American tuna fleet that fishes in the eastern Atlantic consists primarily of purse seiners of 80 to 1,800 metric tons carrying capacity of fish. Home bases for U.S. vessels are in California and Puerto Rico; the eastern Atlantic is only one of several areas where the vessels fish in a year. Each seiner has upwards of 20 fish-holding wells that freeze and store an average of about 60 metric tons of tuna per well.

The fishing season in the eastern tropical Atlantic, while year round for most fleets, begins about July and usually ends in November-December for most American vessels. The American vessels generally fish in close proximity to each other, although they are operated by independent captains. Their catch consists of yellowfin, Thunnus albacares, and skipjack, Katsuwonus pelamis, tunas primarily and some bigeye tuna, T. obesus, and incidental catches of little tunny, Euthynnus alletteratus, frigate and bullet mackerels, Auxis spp., and rainbow runner, Elagatis bipinnulata. In 1967-69, more than half the catch was yellowfin tuna; since 1969, skipjack tuna

has been the dominant species in the catch (Sakagawa and Lenarz 1972). Virtually all the U.S. catch is returned to the United States aboard the seiners or aboard transshipment vessels for processing, canning, and marketing. Transshipments were made in 1970-74.

Monitoring of the American catch to assess stock abundance was initiated by the National Marine Fisheries Service (NMFS), NOAA, in 1968 and continued annually since then. Catch, effort, and length-frequency samples are collected by NMFS representatives and under contract by the Inter-American Tropical Tuna Commission (IATTC) representatives. Summaries of catch and effort data were reported in Sakagawa and Lenarz (1972) and Sakagawa (1974). This report presents a description of procedures used to estimate the length composition of tunas in the American catch and the estimated length composition of tunas caught in 1968-74.

#### SAMPLING PROCEDURES

Tuna catches were sampled for length-frequencies aboard the seiners during unloadings at canneries in California and Puerto Rico in 1968-74, and during unloadings at freezer storage facilities and onto transshipment vessels in west Africa in 1971-73. Samples were also obtained from transshipment vessels that unloaded at canneries in California and Puerto Rico.

Sampling in west Africa was particularly critical in 1971 because in that year, and in 1970 to a lesser degree, large yellowfin and bigeye tunas with presumably high mercury content were selectively shipped to Europe, where a higher mercury content was acceptable, rather than to the United States. Samples taken only in California and Puerto Rico in those years were therefore biased.

Sampling in west Africa also presented the opportunity of sampling the transshipped catch before it was mixed in the holds of the transshipment vessels. Upwards of 700 metric tons of fish have been transported in

<sup>&#</sup>x27;Southwest Fisheries Center, National Marine Fisheries Service, NOAA, La Jolla, CA 92038.

<sup>&</sup>lt;sup>2</sup>Southwest Fisheries Center, National Marine Fisheries Service, NOAA, La Jolla, CA 92038; present address: National Marine Fisheries Service, NOAA, P.O. Box 2223, Main Station, Mayaguez, Puerto Rico 00708.

<sup>&</sup>quot;The fishing operations of Canadian, Dutch (based in Willemstad, Netherlands Antilles), Panamanian, and U.S. boats fishing in the eastern tropical Atlantic are monitored as a unit by the Inter-American Tropical Tuna Commission. "American" in this report refers to this fleet, which in 1968-73 consisted of at least 83% U.S. seiners.

a hold of a transshipment vessel. The transshipped catches of individual seiners are kept separate, but an entire seiner's catch, which is usually caught in several areas and over several months, is generally loaded into a single hold.

## Length-Frequency Samples

The sampling procedures were virtually the same as those recommended by Hennemuth (1957) for the eastern tropical Pacific fishery, i.e., a stratified, by area and month, two-stage subsampling procedure (Cochran 1963) was used. The boundaries of the areas (Fig. 1) were drawn according to the distribution and concentration of fishing effort of the American fleet.

The first stage of the sampling was to choose the well (or hold if a transshipment vessel\*) to sample. The second stage was to draw from the selected well a random sample of each species (yellowfin, skipjack, and bigeye tunas). Ancillary information, such as well number and catcher vessel name, was recorded for each sample. The date, location (NMFS area — Fig. 1), and tonnage of the catch sampled were obtained from logbooks after the samples were drawn.

Before 1972, samples were obtained on an opportunistic basis and the sample size varied (10 to 300 fish). Since 1971, a goal of 6 skipjack samples and 12 yellowfin samples of 50 fish each from each NMFS area and each fishing month was established in an attempt to ensure a more complete area-month coverage. The larger number of samples for yellowfin tuna was required because of the greater variability in sizes of this species (Hennemuth 1957). This goal, however, was not attained in any of the years.

#### Total Catch by NMFS Area-Month

Total catch, by species and month, of tunas caught in the Atlantic by American vessels is tabulated annually by the IATTC from landing receipts. Logbook information on estimated catch by species, 1° area, date, and well number in which the catch is stored for each net set is also collected by the IATTC from virtually the entire American fleet. This logbook information was used to identify those seine sets that contributed to the catch in wells that were sampled and also to prorate the total catch by species of the entire fleet into catch by NMFS area-month strata.

#### ANALYTICAL PROCEDURES

Different areas apparently contain different sizes of fish, at least for yellowfin tuna in the eastern tropical Atlantic (International Commission for the Conservation of Atlantic Tunas 1974a), and the stratified sampling procedure, by month and area, was designed to account partly for this difference. Sizes of fish in the total

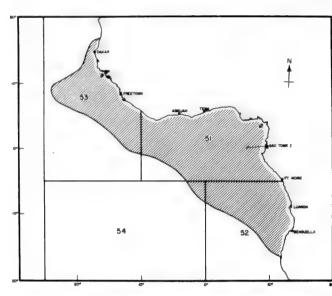

Figure 1.—Map of the eastern tropical Atlantic where American seiners fish for tropical tunas (shaded area). Numbered statistical areas used in this report are shown.

American catch were estimated from the stratified length-frequency samples and catch.

When a sample is drawn from a well, complete information on date, location, and tonnage of catch is not always available; complete information is obtained later from the ship's logbook. Fish that may have been caught in different strata were, consequently, sometimes drawn in a single sample. These samples were not used in our analysis unless 75% or more of the tonnage in the well was caught in a single NMFS area-month stratum. Because of this rule, virtually all samples from transshipment vessels were not used in this study. Analyses currently underway which contain a special stratum for transshipment samples may lead to new procedures for utilizing much of the rejected samples.

#### Weighting Factor

The sample size was fixed and not proportional to the numbers of fish in the well. Each sample was therefore weighted by a factor (number of fish) based on the species tonnage and average weight of fish in the well or, when this was unavailable, on the species tonnage and average weight of fish in seine sets that contributed to the catch in the sampled well.

### **Substituting Samples**

Samples were unavailable for all area-month strata in which the fleet caught fish. For strata without samples, it was necessary to make assumptions about the catch and substitute samples from adjacent strata, within year to estimate the sizes of fish caught by the fleet. Substitution was on the basis of the following rules: 1) use same month and adjacent areas; 2) use same area and adjacent months; 3) use adjacent months and adjacent

<sup>&#</sup>x27;It is not uncommon to find several species stored in a well. The fish are partially thawed in the wells before unloading at the canneries or onto a transshipment vessel. Measurements were made on partially thawed fish.

areas. These rules are ordered according to priority and are based on the assumption that differences in sizes of fish from widely separated areas or months are greater than differences in sizes of fish from adjacent areas or months.

In Tables 1 and 2 the area-month strata with substituted samples are shown for yellowfin and skipjack tunas caught in 1968-74. About 20 to 60% of the strata in which yellowfin tuna were caught and about 10 to 60% of the strata in which skipjack tuna were caught had no samples and substitutes were necessary (Table 3). In terms of tonnage, substitutions were required for 2 to 29% of the total yellowfin tuna catch and 1 to 17% of the total skipjack tuna catch.

The poorest sampling coverage of yellowfin and skipjack tunas was in 1970. In that year, representative sampling was difficult because large yellowfin and bigeye tunas were transshipped in west Africa to foreign ports and not sampled. The best sampling coverage, in terms of tonnage, was in 1969 for yellowfin and 1971 for skipjack tuna.

## **Estimating Length Composition of Catch**

Length-frequency of fish in the total catch by species was computed by summing estimates for each areamonth stratum. The following procedures were used for the stratum estimates:

1. The weight (w in kilograms) of each fish was estimated from length (l in centimeters) based on the appropriate length-weight equation (Lenarz 1974) shown below. The average weight ( $\bar{w}_i$ ) of fish in the sample,  $i=1,2,\ldots,k$ , was then estimated.

Table 1.—Catch (metric tons) and number of length-frequency samples of yellowfin tuna by NMFS area-month strata. Samples substituted in strata without samples are identified in parentheses.

# ESTIMATES OF LENGTH COMPOSITION OF CATCHES

#### Yellowfin Tuna

The estimated length compositions of yellowfin tuna in the 1968-74 catches by month strata, all areas combined, are shown in Appendix Tables 1 to 7. Area differences are presumed to be not as significant as monthly differences within a year.

As many as four modal groups are found in the lengthfrequency distributions, but only two or three are prominent (Fig. 2). The prominent modes correspond to the apparent entering year class (approximately 33 to 47 cm long), 1-yr-old (48 to 85 cm long), and 2-yr-old (86 to 123 cm long) fish. The modal size of the apparent entering year class is peculiar in that it differs from the modal size of the 1-yr-old fish by about 18 cm. According to the growth curve for Atlantic yellowfin tuna of Le Guen and Sakagawa (1973), the difference should be about 57 cm if the two groups are 1 yr apart. Some possible causes for this difference are: 1) there is extreme sampling bias of the entering year class, and perhaps even of 1-yr-old fish in the catch, owing to differential availability or vulnerability; 2) the entering year class in fact represents slower growing or later hatching fish of the same year class as the 1-yr-old fish, i.e., from multiple spawnings (Richards 1969); or 3) that the growth curve of Le Guen and Sakagawa (1973) is incorrect. Both 1) and 2) are probably the major causes for the difference. Hennemuth (1961) similarly identified length modes that were less than a year apart in age and presumably from identical year classes or subpopulations of yellowfin tuna from the eastern tropical Pacific.

In 1968-74, about 0.2 to 1.1 million yellowfin tuna were caught annually by the American fleet in the eastern tropical Atlantic. The age-frequency distributions of the catches (Table 4), based on analysis of modal progression and the growth curve of Le Guen and Sakagawa (1973), indicate that the dominant age group was 1-yrold fish in 1968 and 1970-74, and 2-yr-old fish in 1969.

The catch of 1969 is unusual compared to that of the other years. Besides the dominance of 2-yr olds in the catch of that year, the 1969 catch (in weight) of yellow-fin tuna was the highest recorded for the American fleet and virtually all (98%) was taken in NMFS area 51. About 90% of the catch, furthermore, was from pure yellowfin schools, the remainder from mixed yellowfin-skipjack schools. In the other years, a smaller percentage (61 to 75%) of yellowfin tuna was caught in area 51 and only about 60% of the catch was from pure yellowfin schools. Yellowfin tuna in mixed yellowfin-skipjack schools are generally smaller than in pure yellowfin schools

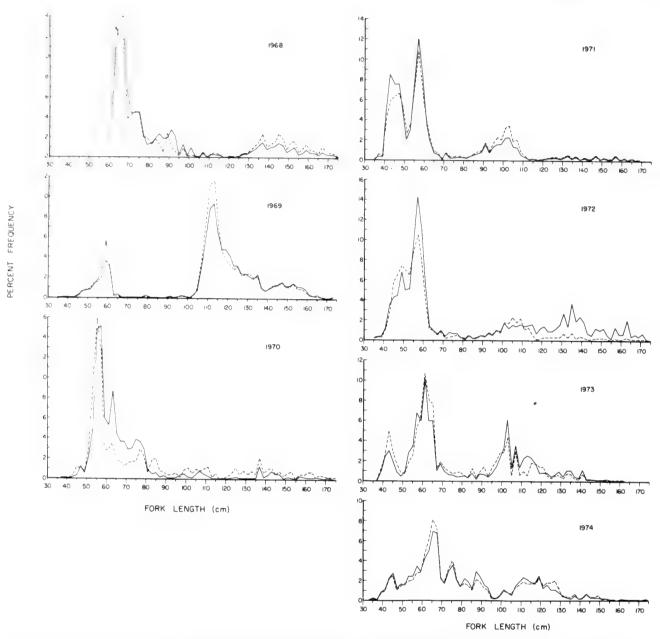

Figure 2.—Estimated length composition of yellowfin tuna caught by American seiners in the eastern tropical Atlantic, 1968-74. (Solid line — stratified procedure; dashed line — unstratified procedure.)

(Calkins 1965). The predominance of large yellowfin tuna (>100 cm) in the 1969 catch could have been caused therefore by the high percentage of pure schools fished in that year.

## Skipjack Tuna

The catch of skipjack tuna by the American fleet markedly increased from 3,180 metric tons in 1968 to 22,290 metric tons in 1973, then decreased to 19,970 metric tons in 1974 (Table 3). This represents for skipjack tuna an estimated 1.2 million in 1968, 12.8 million in

1973, and 10.6 million in 1974. The estimated length composition of the 1968-74 catches by month strata, all areas combined, are shown in Appendix Tables 8 to 16.

Two apparent age groups, probably 1-yr-old (31 to 55 cm long) and 2-yr-old (56 to 67 cm long) fish, contributed to the catch (Fig. 3). The dominant group was 1-yr-old fish in all years except 1969 (Table 5).

The dominant modal length in the skipjack catch decreased from about 50 to 55 cm in 1968-70 to about 45 cm in 1971-74 (Fig. 3). This decrease, while relatively small, occurred with the discovery by the American fleet in 1971 that skipjack fishing is good off Angola (NMFS area 52) during the fall months. Before 1971 most of the

Total		358,900	643,700	1,110,800	460,100	1,414,600	245,900	417,200			

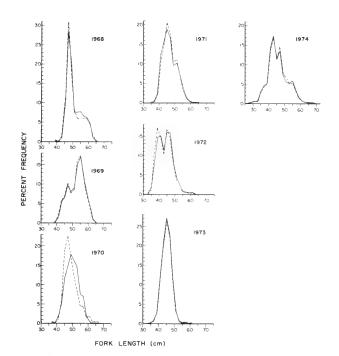

Figure 3.—Estimated length composition of skipjack tuna caught by American seiners in the eastern tropical Atlantic, 1968-74. (Solid line — stratified procedure; dashed line — unstratified procedure.)

American catch was made in the Gulf of Guinea and only about 3 to 21% of the skipjack tuna was caught in area 52. Since the discovery in 1971, as much as 98% of the annual American catch of skipjack has been taken from area 52.

## Bigeye Tuna

Bigeye tuna are not often available to the surface fisheries (purse seine and pole-and-line) of the eastern tropical Atlantic. This species is sometimes confused with yellowfin tuna and catches may have been included with yellowfin tuna catches, but the amount is probably small. The American fleet reported bigeye tuna catches only in 1968 and 1971-74. A few length-frequency samples were collected in those years (Table 6). Because the samples were few, estimates of the length composition of the catch were based on all samples combined without stratification, i.e., all catches and samples pooled and one estimate calculated for each year (Appendix Table 17).

About four major modal groups (39 to 51 cm, 52 to 73 cm, 74 to 105 cm, and 106 to 131 cm) can be identified in the length-frequency distributions (Fig. 4). These groups apparently represent age groups of 1 to 4 yr, based on

Table 5.—Estimated age composition of skipjack tuna caught by the American purse seine fleet in the eastern tropical Atlantic.

Age Approximate group length (cm)		Estimated catch (numbers) by year								
		1968	1969	1970	1971	1972	1973	1974

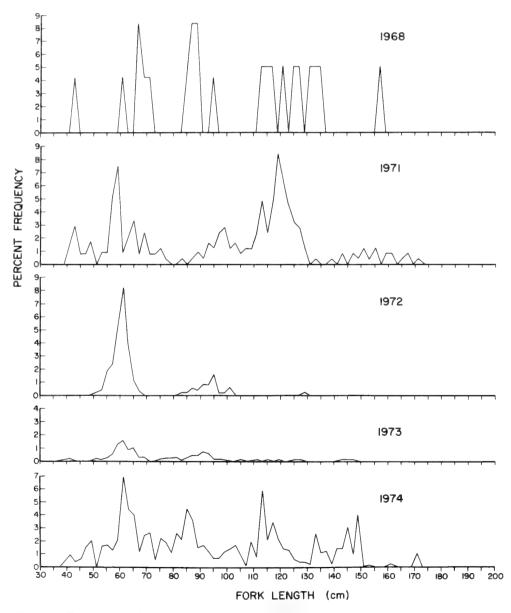

Figure 4.—Estimated length composition of bigeye tuna caught by American seiners in the eastern tropical Atlantic, 1968 and 1971-74.

Champagnat and Pianet's growth curve for Atlantic bigeye tuna.

The estimated total number of bigeye tuna caught by the American fleet in 1968 and 1970-74 ranges from about 500 to 41,200 fish. The largest catch was in 1974, the smallest in 1968.

## SOURCES OF BIAS IN THE ESTIMATES

Several possible sources of bias in the sampling, weighting, and substitution procedures could have significantly influenced the estimated length-frequency distributions of the catches. Some of the sources are discussed below.

## Sampling Bias

Hennemuth (1957) found a slight size-depth stratification of skipjack tuna but none for yellowfin tuna in wells he examined. He mentioned that stratification could result from settling of large fish to the bottom of the well or from different schools of fish of different sizes packed in a layer fashion.

Early in our sampling program, size-depth stratification was recognized as a possible source of error and steps were taken to reduce the influence of this error by limiting sampling to wells that did not appear to contain fish that were stratified by size and depth. How effective this measure was is not known.

A more serious sampling bias was introduced in 1970 with the discovery that tunas, particularly large specimens, contain high levels of mercury which the Food and Drug Administration of the United States deemed unacceptable for U.S. markets. Canneries in the United States, therefore, limited their purchases of large fish, and American fishermen were forced either to not land large tunas or to sell the large tunas to foreign markets where the acceptable level of mercury contamination was higher. Because large yellowfin and bigeye tunas caught off Africa in 1970 and 1971 were selectively sold and transshipped from west African ports directly to foreign buyers, fish landed in the United States were biased towards the smaller fish. This bias probably affected our estimates for 1970. Estimates for 1971 were not affected because catches transshipped to foreign ports were sampled in west African ports prior to transshipment.

## Weighting Bias

Some of our length-frequency samples were weighted by a factor (number of fish) based on the total tonnage and average weight of fish in sets that contributed to the catch in the sampled well. As indicated earlier, this technique was used because the sample size was not proportional to the numbers of fish present and the amount of tonnage in the well was not known. The use of the total tonnage, instead of the tonnage in the sampled well only, to base a weighting factor introduced a bias of overweighting the samples. For example, a sample from a well containing 20 tons of fish from a 80-ton set A and 40 tons from a 40-ton set B would have a weighting factor based on 120 tons, causing the sample to be disproportionately weighted by the catch of set A.

We examined this bias with the August 1973 yellowfin tuna catch of area 52 (Table 1) in which the actual tonnages of fish in the three sampled wells were available. A biased estimate length composition of the catch was derived with weighting factors based on tonnages of 127, 41, and 17 for the three samples. An unbiased estimated length composition of the catch was derived with weighting factors based on the actual tonnages in the sampled wells of 60, 20, and 15, respectively. The unbiased and biased estimated length compositions of the catch are not very different (Fig. 5). However, the total

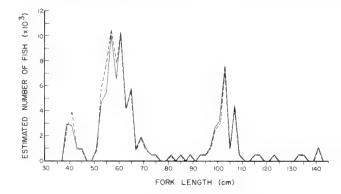

Figure 5.—Estimated length composition of yellowfin tuna caught in August 1973 in NMFS area 52. (Solid line — biased weighting factors; dashed line — unbiased weighting factors.)

estimated number of yellowfin tuna is 7% higher in the unbiased than in the biased estimate, owing to the greater numbers of small fish (<61 cm) in the unbiased estimate.

#### **Substitution Bias**

Of all the possible sources of bias in our estimates, substitution bias perhaps is the most serious. As indicated earlier, 11 to 61% of the strata were not sampled and required substitution of samples from adjacent strata. Furthermore, not all of the sampled strata were sampled adequately. Between 20 to 43% of the strata sampled for yellowfin tuna and 0 to 33% of the strata sampled for skipjack tuna were sampled only once. These samples were also used in the substitution procedure, at times applied to a large catch (Table 7).

The effects of our substitution procedure and single samples on the estimated length composition of the catch were examined with the 1970 data. In that year, sampling coverage was poorest. In Figures 6 and 7, we show the estimated length composition by month using substitutions and also the portion of the composition derived from strata with two or more samples only. In general, the results indicate that substitutions affected

<sup>&</sup>lt;sup>6</sup>Champagnat, C., and R. Pianet. Croissance du patudo (*Thunnus obesus*) dans les regions de Dakar et de Pointe. Unpubl. manuscr., 7 p. Centre de Recherches Oceanographiques, B. P. 2241, Dakar, Senegal.

principally the estimates of fish caught at the beginning (May) and end (September-November) of the 1970 fishing season. The effects are greater for yellowfin tuna (Fig. 6) than for skipjack tuna (Fig. 7).

### DISCUSSION

Estimates of length composition of the American catches of yellowfin and skipjack tunas from the eastern tropical Atlantic have been published in the data records of the International Commission for the Conservation of Atlantic Tunas (1973; 1974b, c). The published estimates were based on preliminary data on total catches and on a stratified procedure with unweighted samples; consequently, they underestimated the numbers of fish

caught and are not comparable to our estimates. Our estimates were based on total catches and on weighted samples. We consider them to be more accurate than those published in the data records.

The stratified procedure was used in our study to gain greater precision in our estimates. However, in years when sampling coverage was poor, the stratified procedure probably was inappropriate and may have distorted the results. In such circumstances, the unstratified procedure may have been more appropriate. Estimates based on the unstratified procedure are shown by dashed lines in Figures 2 and 3.

The stratified procedure is the most desirable for estimating the size composition of the catch of tunas because it can result in precise estimates (Hennemuth 1957). The choice between the unstratified and stratified procedures should be based on sampling cost as well as precision. For the American tuna catches from the eastern tropical Atlantic, the sampling cost is currently not much greater with the stratified than the unstratified procedure. The choice then is to use the stratified procedure which can account for area-time differences in the sizes of fish caught. If the sampling coverage is poor, however, particularly for yellowfin tuna with a wide range of sizes, the full advantage of the stratified procedure is lost and the estimates would not be very different from those based on the unstratified procedure. In this case, the procedures are equally precise in estimating the size composition of the catch and either procedure can be used without fear of losing more precision from one than the other.

#### ACKNOWLEDGMENTS

We thank C. J. Orange of the IATTC who supervised the collection of much of the data used in this report. W. H. Lenarz of the Southwest Fisheries Center (SWFC) initiated the sampling program and generously provided information on the sampling design. W. W. Fox, Jr. and W. H. Lenarz of SWFC; Z. Suzuki of the Far Seas Fisheries Research Laboratory, Fisheries Agency of Japan; and P. K. Tomlinson of the IATTC read the manuscript and offered helpful comments.
